### 1. INTRODUCTION

This application note details the interface of Crystal Semiconductor's CS5521/22/23/24/28 Analog-to-Digital Converter (ADC) to an 80C51 microcontroller. It includes the complete code written for the CDB5521/22/23/24/28 Evaluation Board, which also interfaces the 80C51 to a PC. All algorithms discussed are included in Section 7. "Appendix: 80C51 Microcontroller Code" on page 9.

### 2. ADC DIGITAL INTERFACE

The CS5521/22/23/24/28 interfaces to the 80C51 through either a three-wire or a four-wire interface. Figure 1 depicts the interface between the two devices. This software was written to interface to Port 1 (P1) on the 80C51 with either type of interface. The ADC's serial port consists of four control lines:  $\overline{CS}$ , SCLK, SDI, and SDO.

$\overline{CS}$ , Chip Select, is the control line which enables access to the serial port.

SCLK, Serial Clock, is the bit-clock which controls the shifting of data to or from the ADC's serial port.

SDI, Serial Data In, is the data signal used to transfer data from the 80C51 to the ADC.

SDO, Serial Data Out, is the data signal used to transfer output data from the ADC to the 80C51.

### 3. SOFTWARE DESCRIPTION

This note details all of the algorithms contained in the CDB5521/22/23/24/28 Evaluation Board software. The software is written for the 80C51 microcontroller on the evaluation board. The more important communication algorithms are written in

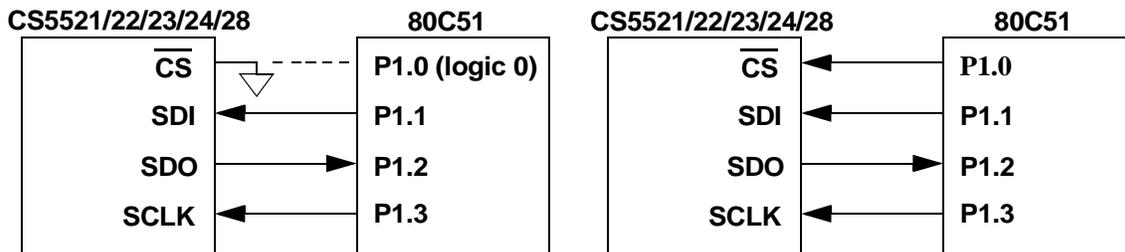

Figure 1. 3-Wire and 4-Wire Interfaces

80C51 assembly language, providing a good set of tools for both C and assembly programmers to build their own designs upon. While reading this application note, please refer to Section 7. “Appendix: 80C51 Microcontroller Code” on page 9 for the code listing.

### 3.1 Main Program Loop

The *main* loop of the program is responsible for calling all other algorithms and controlling the program flow. Figure 2 depicts the data flow of the *main* loop. When the evaluation board is first powered up, or after a system reset, the microcontroller and ADC are set up by calling the *initialize* routine. The value present on the DIP switches is then checked. If this value is anything other than zero, the program goes into test mode. If the value is equal to zero, the program goes into a continuous loop, where it receives commands from the PC, decodes them, and performs the desired actions.

### 3.2 Initialize

*Initialize* is used to configure the microcontroller and the ADC to the proper settings that will allow the PC to control the ADC indirectly through the microcontroller. The 80C51’s port P1 is configured as depicted in Figure 1 (for more information on configuring ports refer to the 80C51 Data Sheet). Next, port P2 is written twice, once with all zeros and once with all ones, with a delay in between to control the LEDs attached to the port and inform the user that the board has been reset successfully.

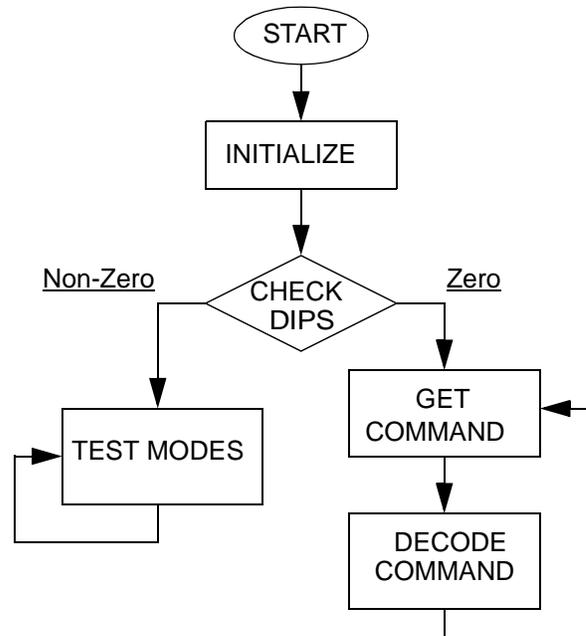

Figure 2. Software Flow Diagram

Port P3 is then set up to use the 80C51’s internal UART to interface to the PC at 9600 baud, no parity bit, eight data bits, and one stop bit. To allow time for the ADCs oscillator to start up, a delay state is entered (oscillator start-up time is typically 500ms). After this delay, the ADC is ready to accept data. However, it is a good idea to reset the ADC’s serial port before communicating with it. To reset the serial port on the ADC, SDI is asserted, and 255 SCLKs are provided. SDI is then cleared, and one final SCLK is provided (this is a slight overkill, as only 15 bytes of logic 1’s followed by a

final byte with its LSB at logic 0 are needed to reset the serial port). This places the ADC in the command state, where it awaits a valid command. Finally, before returning to the *main* routine, the mode pin is queried to determine whether a three or four-wire interface is being used.

### 3.3 Transfer Data To/From ADC

Transferring data to and from the ADC is done through the *transfer\_byte* and *receive\_byte* functions. *Transfer\_byte* takes one byte of input and sends it to the ADC one bit at a time (MSB first) by applying the bit information to P1.1 (SDI) and then pulsing P1.3 (SCLK). This is repeated eight times to transfer the entire byte of data to the ADC. *Receive\_byte* works in just the opposite direction, obtaining byte information MSB-first on the P1.2 (SDO) line as it provides the clock on P1.3. The functions *write\_to\_register* and *read\_register* make use of these byte transfer functions to send and receive internal register information in the proper order from the ADC. *Write\_to\_register* writes four bytes of information to the ADC using *transfer\_byte*. The command byte is written first, followed by the high, middle, and low bytes of the 24-bit register word. *Read\_register*, on the other hand, sends a command byte to the ADC using *transfer\_byte*, and then obtains the 24-bit register word by calling *receive\_byte* three times in succession. Due to the conversion time delay, reading conversion data requires a slightly different method than reading register information. The *read\_conversion* algorithm is designed for this purpose. The configuration register is read and stored in memory using the *read\_register* command. The LP, RC, and MC bits are then masked to zero, and the register is written using *write\_to\_register*. The command to start a conversion is then written using *transfer\_byte*, and SDO is polled until the ADC indicates that the conversion is complete. Once a valid conversion has been obtained, eight zeros are sent to the ADC with *transfer\_byte* to start the transfer of data, at which time *receive\_byte* is

called three times to obtain the data word (see Figure 3 for more detail on how the information is organized among the three bytes) Figure 6 shows the conversion data timing.

0 - always zero, 1 - always 1

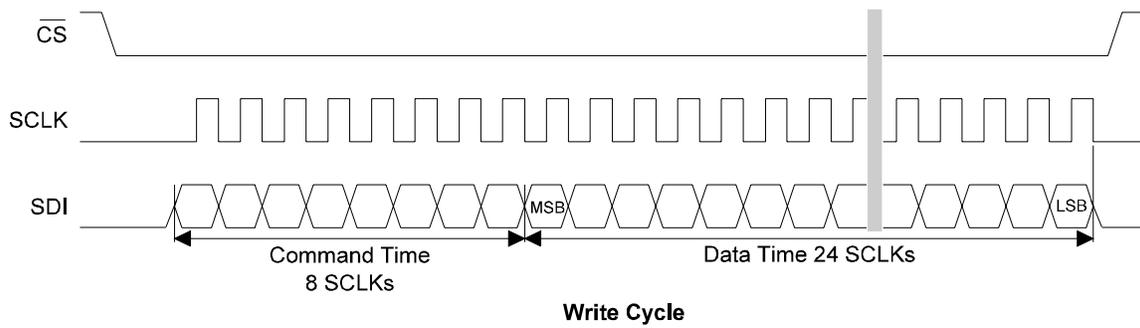

CI1, CI0 - Channel Indicator Bits

OD - Oscillation Detect, OF - Overflow

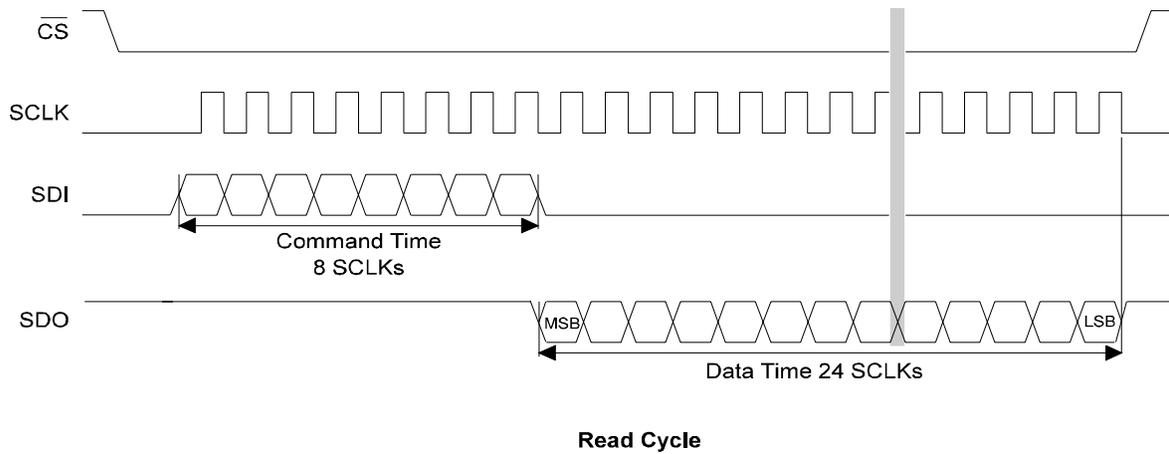

Figure 3. Bit Representation/Storage in 80C51

### 3.4 Transfer Data To/From PC

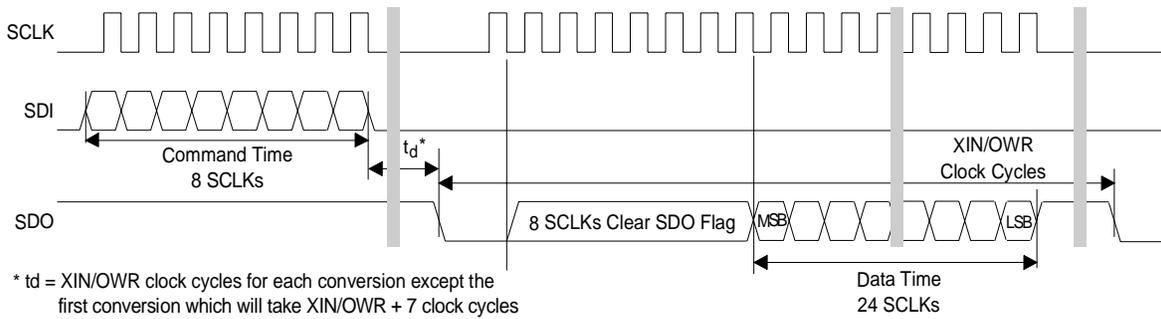

Transferring data to and from a PC through the 80C51's serial port is accomplished with the routines *txser* and *rxser*. These two routines rely upon status bits in the 80C51's Serial Control Register (SCON, located at address 0x98 Hex). *Txser* transfers data to the serial port by first polling TI (Transfer Interrupt, bit 1 in SCON) until the 80C51's serial buffer is empty, and ready to receive information. Once TI is at a logic high level, the software clears the TI bit and moves the byte to be transferred into the 80C51's serial buffer, where it is transmitted to the PC LSB first. *Rxser* receives a byte in a similar fashion, by polling RI (Receive Interrupt, bit 0 in SCON) until there is valid data available in the 80C51's serial buffer. When RI is at a logic high level, the data is transferred out of the serial buffer to an immediate memory location.

**Figure 4. Write-Cycle Timing**

**Figure 5. Read-Cycle Timing**

\*  $t_d$  = XIN/OWR clock cycles for each conversion except the first conversion which will take XIN/OWR + 7 clock cycles

**Figure 6. Conversion/Acquisition Cycle Timing**

### 3.5 Decoding PC Commands

The *decode\_command* routine is where most of the functionality of the program lies. It consists of many smaller routines to direct the flow of data to the proper locations. *Decode\_command* accepts information from the PC, decides which tasks need to be done based on that information, and carries out those tasks accordingly. This is accomplished through the use of a very large switch statement, based on the input command byte, which tests for every possibility and performs the appropriate routines shown in Section 7. “Appendix: 80C51 Microcontroller Code” on page 9.

**Write Register** - If the PC has sent a command to write to a specific register in the CS5521/22/23/24/28, three more bytes are received from the PC using *rxser* (24-bit data is always transferred via the UART in the order: low byte, middle byte, high byte). Then the information, including the command byte is sent to the converter using the *write\_to\_register* function. In contrast with the PC serial data, data transferred to or from the ADC is always in the order: high byte, middle byte, low byte.

**Write Channel Setup Registers** - In the case that the PC requests to write to the Channel Setup Registers (CSRs), the program receives another byte from the PC to find out how many registers to write to. The command word 0x05(HEX) is sent to the ADC to begin writing to the registers. The data is received from the PC using *rxser*, and sent directly to the ADC using *transfer\_byte*. This process of receiving data from the PC and transferring it to the ADC is repeated until the requested number of bytes has been sent to the PC.

**Read Registers** - When the decoded command is asking to read the ADC’s internal registers, *read\_register* is called, using the command sent from the PC. The information obtained by this function is then sent to the PC using *txser*.

**Read Conversion Data FIFO** - To read the conversion data FIFO, the sample size requested, the conversion channel, and the loop bit status are received from the PC, in that order. The conversion channel is then sent to the ADC to begin a conversion, and SDO is polled until it falls, indicating that the conversion is complete. At this time, a byte of zeros is sent to the ADC to initiate the data transfer, and the program loops through to receive each 24-bit conversion word and send it to the PC, for as many times as the sample size that has been requested. If the LP bit is set, then another sample set is received from the ADC, but not sent to the PC.

**Read Channel Setup Registers** - To read the CSRs, this algorithm first obtains the number of registers to read from the PC using *rxser*. It then transfers the 0x0D(HEX) command to the ADC, indicating that the CSRs are to be read. Next, the individual registers are read from the ADC and sent to the PC until the number of registers specified by the PC command has been met.

**Normal Conversions** - For a normal conversion using any Setup, the *read\_conversion* subroutine is executed using the appropriate command word. The data is then sent directly to the PC using *txser*.

**Self Calibration** - To perform a self-offset or self-gain calibration using any Setup, the appropriate command word is sent to the ADC, and SDO is polled until the calibration is complete to avoid sending a new command when the ADC is busy.

**System Calibration** - System-offset and system-gain calibrations use the same procedure as self calibration, but are separated in the code to set the two command sets apart from one another.

**Variable Number of Normal Conversions** - This routine is used when a set of samples is requested from the PC (as opposed to a single sample). The sample index is obtained from the PC, as well as the Setup to be used. The *decode\_sample\_index* routine is then called to find out exactly how many conversions to perform. The conversion channel

data is then transferred to the ADC, and SDO is polled until the conversion is ready. A byte of zeros is then transmitted to the ADC to begin the data transfer, and the data word is received. The data word is then sent to the PC, and the process is repeated until the sample size has been reached. Once enough samples have been collected and transferred to the PC, a command byte consisting of all ones is sent to the ADC to instruct it to stop converting data, and the final conversion word is received from the ADC and discarded.

**Variable Number of Offset or Gain Calibrations -** When more than one offset or gain calibration is requested, the software obtains a sample index, the type of calibration (self or system), and which Setup is being used to calibrate from the PC. *Decode\_sample\_index* is called to determine the actual number of calibrations to be performed, and then the calibration type is sent to the ADC. SDO is polled until the calibration is completed, and then the calibration register is sent. The calibrated register is returned by the ADC, and sent to the PC. This process continues until the number of calibrations requested have been performed.

**Serial Port Initialization -** This routine re-initializes the serial port on the ADC if it is requested. To accomplish this, the SDI pin is set to a logic high level, and SCLK is pulsed 255 times. SDI is then brought low and a single SCLK pulse is sent. This initialization routine is the same as what is done within the start-up *initialize* command, but is limited to the serial port on the ADC.

**Reset Converter Via RS and RV Bits -** This routine resets the ADC, and returns all of its internal registers to their initial states. The command 0x03 followed by 0x800000(HEX) is sent to the ADC, which sets the RS (Reset) bit and nothing else. Then the 0x0B(HEX) register is read, and the low byte is masked for the RV (Reset Valid) bit. If a valid reset has occurred, the RS bit is cleared. If no valid reset has occurred, the routine continues to

cycle and poll the RV bit until the reset is successful.

**Read Output Latch Pins -** The ADC's output latch pins (A0 and A1) are connected to pins P1.4 and P1.5, respectively, on the 80C51. If the PC requests the status of these pins, they are read from the proper pins and transmitted to the PC.

**Arbitrary Read -** This routine is used to read any number of bytes from the ADC and return them to the PC. The number of bytes requested is obtained from the PC, and then bytes are successively read from the ADC and transmitted to the PC until that number has been reached.

**Arbitrary Write -** This routine asks for one byte from the PC, and transfers it to the ADC.

If none of these conditions are met, the software does nothing but return to the *main* routine.

### **3.6 Sample Index**

When the PC requests an entire sample set, the microcontroller code assumes that it will be sending a sample index. This number, 0-10, is passed to the *decode\_sample\_index* routine to select one of the ten sample set size options. The sample set sizes are based on the FFT algorithms in the PC evaluation board software, which require a sample set size of  $2^N$  samples, and the software's internal limitation of between 16 and 8192 samples. A single sample option is also included, and if none of these are selected, the sample size defaults to zero.

### **3.7 Test Modes**

There are a seven self-test modes built in the controller software, contained in the routine *test\_mode*. These tests allow the user to troubleshoot certain problems that may be occurring with the evaluation board and its software. The test modes are entered by setting the DIP switches to a value greater than zero and resetting the board. This instructs the *main* routine to skip over the normal operation loop and go straight into test mode. To exit any of these rou-

tines, the user must place the DIP switches back into the '000' position and reset the evaluation board. Each of the seven test modes is now described.

**Mode 1, Loop Back Test** - This test is used to check the 80C51's on-chip UART. To perform this test, the user must place HDR7 in loop back position as indicated on the evaluation board, and set the DIP switches to '001'. When this mode is entered, a byte (0xAA) is sent out to the UART and then a byte is received from the UART. A delay is inserted to allow time for the information to be transmitted and received, and then the received byte is compared to the transmitted information. If the received byte is equal to 0xAA(HEX), then the test was successful, and the code calls the *toggle\_all\_leds* routine, which continuously blinks all four LEDs. If the information does not match up, the test failed, and the code branches to the *toggle\_two\_leds* routine, which continuously blinks only the first two LEDs (RESET and COMM).

**Mode 2, Read/Write to ADC** - This mode tests the microcontroller's ability to read and write the internal registers of the ADC. To perform this test, the user sets the DIPs to '010' and resets the board. Upon entering this test mode, the code writes 0xAA0000(HEX) to both the offset and gain registers of Physical Channel 1 (PC1). The information is then read from these two registers, and the high byte of each is compared to the value 0xAA(HEX). If they are both the same, then the test passed, and *toggle\_all\_leds* is called. If either of the registers were not written properly, the test failed, and *toggle\_two\_leds* is called.

**Mode 3, Continuously Acquire Single Conversion** - In this mode, conversions are continuously obtained from the ADC. This test mode is initiated by setting the DIPs to '011'. The first two LEDs are lighted, and the code loops and continuously gathers conversions until the evaluation board is reset.

By probing HDR6 on the evaluation board and using  $\overline{CS}$  as a triggering pin, an oscilloscope or logic analyzer will display how the microcontroller reads conversion data in real-time.

**Mode 4, Continuously Write Gain Register** - In mode 4, the gain register of PC1 is written to continuously. The test mode is entered by setting the DIPs to '100'. The third LED (GAIN\_CAL) is lit, and the code loops and keeps writing to the gain register of PC1 until the evaluation board is reset. By probing HDR6 on the evaluation board and using  $\overline{CS}$  as a triggering pin, an oscilloscope or logic analyzer will display how the microcontroller writes information to the ADC's internal registers in real-time.

**Mode 5, Continuously Read Gain Register** - This mode continuously reads the gain register on PC1. Setting the DIPs to '101' selects this test mode. The odd LEDs (RESET and GAIN\_CAL) are lit, and the code loops through to read from the gain register of PC1 until the evaluation board is reset. By probing HDR6 on the evaluation board and using  $\overline{CS}$  as a triggering pin, an oscilloscope or logic analyzer will display how the microcontroller reads data from the ADC's internal registers in real-time.

**Mode 6, PC to Microcontroller RS-232 Communication Link Test** - This test is performed in conjunction with the PC to verify that the RS-232 link is fully operational on both ends. Setting the DIPs to '110' selects for this test mode. When HDR7 is in the Normal position, the controller receives three bytes of information from the PC, and then echoes them back in the same order that they were received and calls *toggle\_all\_leds*. When HDR7 is in the Loopback position, the three bytes are automatically looped back to the PC through the RS-232 circuitry. The PC software indicates whether this test passes or fails, based upon the bytes it receives back from the board.

**Mode 7, Toggle LEDs** - This mode is used to test the functionality of the LEDs on the evaluation

board, and is entered by setting the DIPs to '111'. Immediately upon entering mode 7, the *toggle\_all\_leds* routine is called to blink the LEDs repeatedly until the board is reset.

#### **4. MAXIMUM SCLK RATE**

A machine cycle in the 80C51 consists 12 oscillator periods or 1 $\mu$ s if the microcontroller's oscillator frequency is 12 MHz. Since the CS5521/22/23/24/28's maximum SCLK rate is 2MHz, additional no operation (NOP) delays may be necessary to reduce the transfer rate if the microcontroller system requires higher rate oscillators.

#### **5. DEVELOPMENT TOOL DESCRIPTION**

The code in this application note was developed using a software development package from Franklin Software, Inc. The code consists of intermixed C and assembler algorithms which are used by the CDB5521/22/23/24/28, a customer evaluation board designed to help customers evaluate the performance of the CS5521/22/23/24/28 devices.

#### **6. CONCLUSION**

This application note describes code that can be used to interface an 80C51 to both the CS5521/22/23/24/28 ADC and a PC. It is divided into two main sections: hardware and software. The hardware interface illustrates both a three-wire and a four-wire interface between the 80C51 and the ADC. The three-wire is *SPI*<sup>™</sup> and *MICROWIRE*<sup>™</sup> compatible. The software, developed with development tools from Franklin Software, Inc., is used in conjunction with the PC evaluation software and the CDB5521/22/23/24/28 evaluation board to provide a system by which the CS5521/22/23/24/28's performance can be evaluated. There are four main routines which interface the CS5521/22/23/24/28 to the 80C51, and provide the communication between the 80C51 and the PC, e.g. *transfer\_byte*, *receive\_byte*, *txser*, and *rxser*. These four routines are written in 80C51 assembly language, and are easily imported into application-specific designs by both C and assembly programmers.

All of the software described in this note is included Section 7. "Appendix: 80C51 Microcontroller Code" on page 9.
